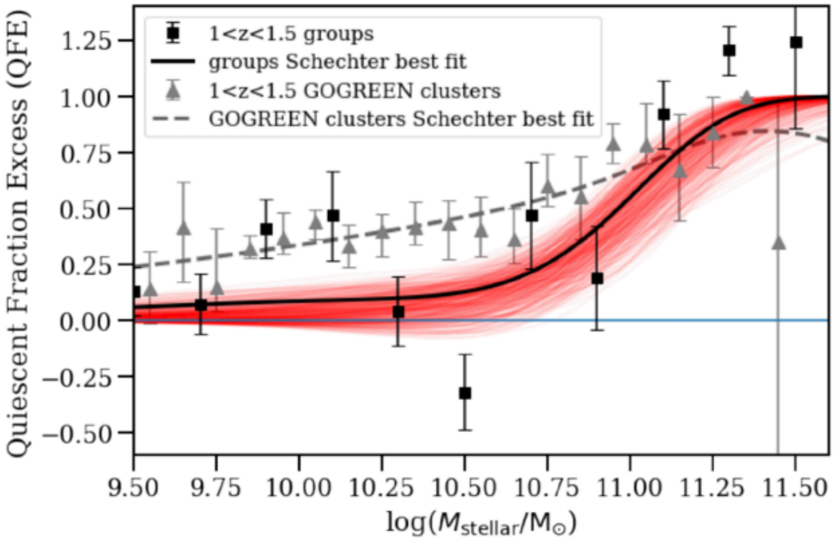
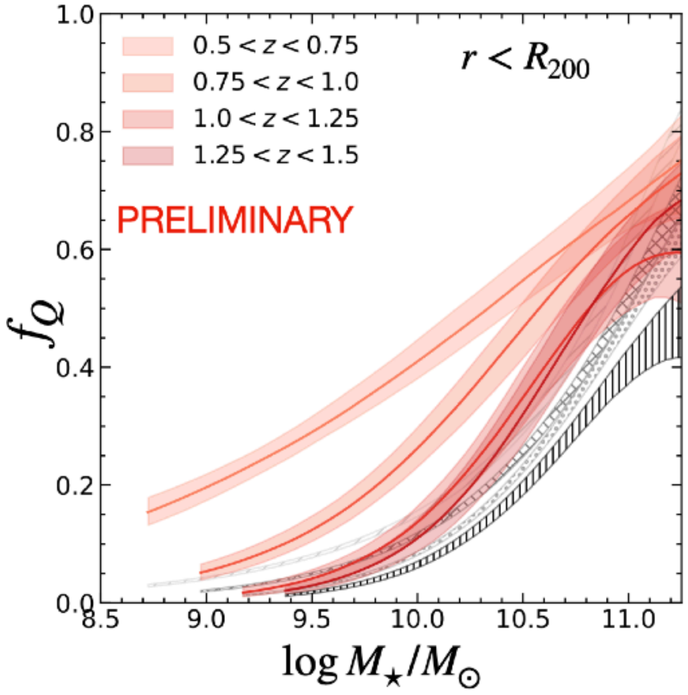
QFE as a function of stellar-mass and redshift

Reeves+21

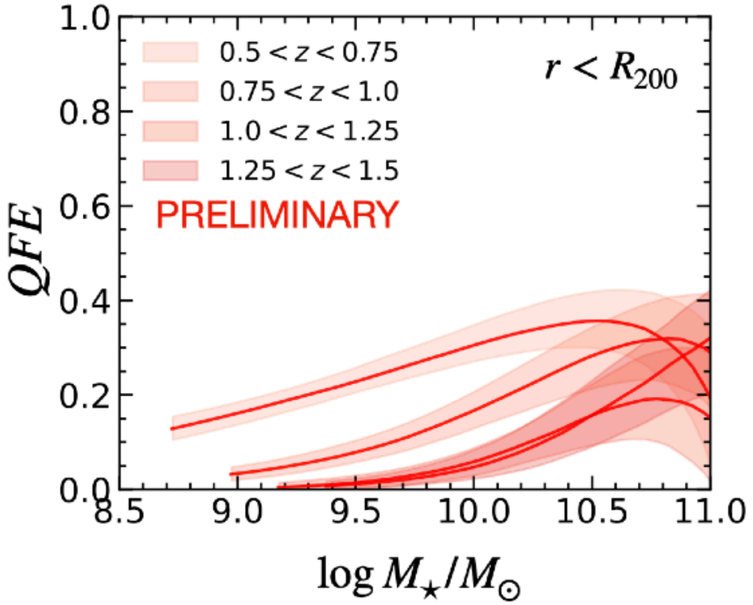


Groups not efficient at quenching lower mass galaxies at $1 < z < 1.5$

REFINE



- The quenched fraction at $M_\star < 10.5$ increases with decreasing redshift $z <$ in galaxy groups



- The QFE $M_\star$ dependence in groups steepens at $z > 1$ due to a lack of quenched low mass galaxies at lower masses — similar to ZFOURGE

In progress — Hierarchical model to fit the redshift, group mass and radial distance on the full REFINE sample

Conclusions

Galaxy surveys both spectroscopic and photometric allow to reconstruct the structure of the cosmic web on large scale and around clusters

The role played by filamentary accretion on cluster and cluster galaxy properties is still relatively unexplored, in particular form an observational point of view

Euclid has a huge legacy potential for pushing our understanding → need to develop / update our tools
